## CORE-COLLAPSE SUPERNOVAE AND HOST GALAXY STELLAR POPULATIONS

Patrick L. Kelly<sup>1,2</sup> and Robert P. Kirshner<sup>3</sup> Draft version October 21, 2011

#### ABSTRACT

We have used images and spectra of the Sloan Digital Sky Survey to examine the host galaxies of 519 nearby supernovae. The colors at the sites of the explosions, as well as chemical abundances, and specific star formation rates of the host galaxies provide circumstantial evidence on the origin of each supernova type. We examine separately SN II, SN IIn, SN IIb, SN Ib, SN Ic, and SN Ic with broad lines (SN Ic-BL). Type Ic SN explode at small host offsets, and their hosts have exceptionally strongly star-forming, metal-rich, and dusty stellar populations near their centers. The SN Ic-BL and SN IIb explode in exceptionally blue locations, and we find that their host galaxies have lower oxygen abundance than the hosts of their respective close spectroscopic cousins, SN Ic and SN Ib. The host galaxies of SN Ic-BL also exhibit strong central specific star formation rates. In contrast, we find no strong evidence for different environments for SN IIn compared to the sites of SN II. We take account of the source of the supernova discoveries, whether from targeted searches or from galaxy-impartial surveys, and show that these results are robust.

Subject headings: supernovae: general — stars: abundances — galaxies: star formation — gamma rays: bursts

## 1. INTRODUCTION

The only SN found in passive, elliptical galaxies are Type Ia (van den Bergh & Tammann 1991). Finding these events in galaxies without ongoing star formation is strong evidence that long-lived progenitors contribute to the observed SN Ia population. SN of other spectroscopic types have been discovered only in star-forming galaxies: that is why we think these SN types are explosions of massive, short-lived stars. Our aim here is to use more detailed information on the hosts to help sort out the origin of the varieties of core-collapse events. Host galaxy measurements have started to identify patterns among the environments of the many spectroscopic types of core-collapse supernovae (e.g., van Dyk et al. 1996; Modjaz et al. 2008; Kelly et al. 2008). Here, we construct a nearby sample of supernova hosts where groundbased images provide useful spatial resolution: for the median redshift in our sample (z  $\sim 0.02$ ), one arcsecond corresponds to 400 parsecs<sup>4</sup>. We use images from SDSS Data Release 8 (DR 8) to measure the color at the supernova sites and to estimate the hosts' stellar masses, and Sloan spectra to determine the hosts' oxygen abundances, specific star formation rate (SFR), and the interstellar reddening. Although these are blunt tools for determining how star formation, stellar evolution, mass loss, and progenitor chemistry produce the diversity of core-collapse phenomena, circumstantial evidence can provide useful clues to these complex processes.

The primary SN spectroscopic classes are organized around evidence of hydrogen and helium features (see

Filippenko 1997 for a review). Young, massive stars with an intact hydrogen envelope at the time of their explosion yield hydrogen-rich spectra, the Type II class. When massive SN progenitors lose their hydrogen-rich shells, the core collapse and subsequent explosions can produce a variety of spectroscopic outcomes. SN Ib have a hydrogen-deficient spectrum that shows helium features, while SN Ic do not show either hydrogen or helium lines. The chameleon SN IIb class shows the hydrogen lines of a SN II at first, but then shows helium lines, suggesting there is only a thin layer of hydrogen on the surface. Line widths are also important. The spectra of SN Ic sometimes show very broad lines, suggesting expansion of the surface at 0.1c: these are the broad-lined SN Ic (SN Ic-BL). Conversely, SN II are sometimes seen with exceptionally narrow lines. These are the SN IIn, which result from interaction between the ejecta and circumstellar matter. SN Ia are a distinct class whose spectra are characterized by the absence of hydrogen and the presence of a broad absorption feature at 6150Å that is attributed to Si. Unlike all the others, they are attributed to thermonuclear explosions in white dwarfs.

Spectra of the SN are reported by their discoverers or, in many cases, by independent teams. The CfA Supernova program aims to obtain spectra of all the SN north of -20° and brighter than 18th mag (e.g., Matheson et al. 2008), following up discoveries made by amateurs and by programs like the Lick Observatory Supernova Search (LOSS: Filippenko 2003). Programs with the MMT, Magellan, and Gemini pursue fainter SN discoveries from the wide-field PAN-STARRS survey (Kaiser et al. 2010). The Palomar Transient Factory (PTF) (Law et al. 2009). a galaxy-impartial search with the 1.2m Oschin Telescope begun in 2009, has discovered and spectroscopically classified more than a thousand SN. Supernova classifications have become more refined over time and the brief reports in IAU Circulars or in catalogs may need to be revisited as new varieties are defined. For this reason, it will be

valuable to archive spectra for future analysis, not just present the classification in an IAU Circular. The CfA spectra, and collections of other spectra organized by the University of Oklahoma and the Weizmann Institute are presently available online<sup>5,6,7</sup>.

With the uniform spectroscopy and u'q'r'i'z imaging of the SDSS, we study the environments of the most populous SN types, identifying a series of strong patterns for stripped-envelope SN types. Section 2 describes the data. Section 3 details the construction of the SN sample, classification of the SN, explains how we categorize SN surveys, and scrutinizes SN discoveries for type-dependent biases. We distinguish between the methods of SN discovery and test hypotheses using only targeted or only galaxy-impartial SN. For a number of two-sample comparisons, patterns only have statistical significance when we merge these two samples, but we find reason in Section 3 to believe that any bias introduced by this combination does not dominate the conclusions we draw. The measurement of host galaxy photometry and spectroscopic oxygen abundances is described in Section 4, our statistical method is described in Section 5, and Section 6 presents the results of our analysis. We compare the relative rates of stripped-envelope SN to Type II with increasing host metallicity to model predictions in Section 7. Section 8 presents a discussion of potential systematic effects. Finally, we discuss our results in Section 9 and present conclusions in Section 10.

#### 2. DATA

The imaging component of the SDSS DR8 spans 14555 square degrees and consists of 53.9 second u'g'r'i'z' exposures taken with the 2.5m telescope at Apache Point, New Mexico. Each frame consists of a 2048 x 1498 pixel array that samples a 13.5' x 9.9' field. The complementary fiber SDSS DR8 spectroscopic survey covers a 9274 square degree subset of the DR8 imaging footprint. Objects detected at greater than  $5\sigma$ , selected as extended, and with r'-band magnitudes brighter than 17.77 comprise the main galaxy sample for spectroscopic targeting. When the r'-band 3" fiber magnitude is fainter than 19 magnitudes, fiber targets must meet additional criteria, and physical constraints limit adjacent fibers

NOTE. — SN remaining of each spectroscopic type after applying inclusion criteria. (1) SN collected in the Asiago Catalog updated through 2010 November 7 with z < 0.023 for targeted discoveries (and, for Table 1, z<0.08 Asiago galaxy-impartial discoveries combined with the 72 Palomar Transient Factory (PTF) core-collapse SN discoveries from March 2009 through March 2010 (Arcavi et al. 2010)) and not classified as Type Ia; (2) SN discovered during period 1990-present; (3) Asiago catalog or PTF SN classification not accompanied by ('?'; ambiguous identification) or (':'; type inferred from light curve not spectrum); (4) calcium-rich SN 2000ds, SN 2003dg, SN 2003dr, and SN 2005E are grouped apart from other SN (Ib+Ic) because of their potentially distinct progenitor population; (5) SN position coordinates in the host galaxy; (6) inside SDSS DR 8 imaging footprint; (7) retrieved SDSS images collectively cover host galaxy without header issue; (8) host galaxy not detected (SN 2006jl (IIn); SN 2006lh (II); SN 2007fl (II); SN 2008bb (II); SN 2008it (IIn); SN 2009dv (IIP); SN 2009lz (IIP); SN 2009ny (Ib); PTF09gyp (IIb)); (9) no contamination from nearby bright stars; (10) no contamination from residual SN light, the sample used for photometry measurements; (11) an SDSS host fiber available and sufficient S/N to classify using BPT diagram, used for extinction measurements; (12) no AGN contamination in SDSS spectrum. Two SN-LGRB had z < 0.08(SN 1998bw and SN 2006aj), and only the host of SN 2006aj was inside the SDSS DR8. The middle and bottom sections of the Table correspond to the 'Photometry' and the 'Spectroscopic' samples, respectively, subsets of the SN remaining after the 'No Host Detected' criterion is applied.

to be no closer than 55" (Strauss et al. 2002) in a single fiber mask. Because of their large angular sizes, nearby galaxies were often 'shredded' into multiple objects by the SDSS object detection algorithm [see Fig. 9 of Blanton et al. 2005], and many of these galaxies were targeted in multiple locations with fibers. Wavelength coverage of the SDSS spectrograph extends from 3800 to 9200 Å. Exposures typically are a total of 45 minutes taken in three separate 15 minute exposures.

## 3. Sample

We assemble our SN samples from discoveries collected in the Asiago catalog (Barbon et al. 1999) through 2010 November 6 and 72 Palomar Transient Factory (PTF) core-collapse SN discoveries from March 2009 through March 2010 (Arcavi et al. 2010). Eight of the SN in the Asiago catalog (all Type II SN) are also among the Arcavi et al. 2010 PTF SN (IAU/PTF: 09ct/09cu; 09bk/09t; 09bj/09r; 09bl/09g; 09ir/09due; 09nu/gtt; 10K/09icx; 10Z/10bau).

#### 3.1. Excluding SN Contamination

We consider images taken during the period from 3 months before to 12 months after discovery to be potentially contaminated by SN light. Arcavi et al. 2010 do

<sup>&</sup>lt;sup>5</sup> http://www.cfa.harvard.edu/supernova/SNarchive.html

<sup>6</sup> http://suspect.nhn.ou.edu/~suspect/

<sup>&</sup>lt;sup>7</sup> http://www.weizmann.ac.il/astrophysics/wiseass/

not report the exact discovery dates of PTF SN, so, for these SN, the contamination window begins three months before the start and ends 12 months after the completion of the search period.

To assemble SDSS frames of each SN host, we first queried the SDSS SkyServer for any frames within 9.75' of the host galaxy center. If none was available without possible contamination from SN light (even with partial coverage not including from the field center), we instead assembled and constructed mosaics from potentially contaminated images. Such mosaics were used only to measure the deprojected offsets of SDSS spectroscopic fibers and the SN site in each host galaxy. We note that a small number of images retrieved from the SDSS server lacked TAN projection header information, making them unusable for our analysis.

### 3.2. Spectroscopic Classes

Our previous work has shown that SN Ic are more strongly associated with bright regions in their host galaxies' g'-band light than are SN Ib (Kelly et al. 2008), indicating that they have a distinct progenitor population, so we group them separately in this analysis. SN IIb and SN IIn subtypes are excluded from the "SN II" sample. A single SN-LGRB, SN 2006aj, meets the sample criteria, but we consider it separately from SN Ic-BL discovered through their optical emission (which have no associated LGRB), as did Modjaz et al. 2008. Today's gamma-ray searches are not sensitive to normal SN explosions.

We exclude SN 2006jc, a peculiar SN Ib with narrow helium emission lines and an underlying broad-lined SN Ic spectrum (e.g., Foley et al. 2007; Pastorello et al. 2007), from our SN Ib statistical sample. The helium emission may reflect the collision of ejecta with a helium-rich circumstellar medium.

From a comprehensive set of spectra, we update the classification of SN 2005az. This SN was discovered approximately seventeen days before maximum and spectroscopically classified three days after discovery as a SN Ic by Quimby et al. 2005a. The Nearby Supernova Factory, from a spectrum taken five days after discovery, suggested it as a Type Ib (Aldering et al. 2005). SNID (Blondin & Tonry 2007) cross correlation, applied to 24 spectra taken by the CfA Supernova Group from approximately ten days before to twenty-five days after maximum, shows that it was a Type Ic explosion.

We group calcium-rich SN 2000ds, SN 2003dg, SN 2003dr, and SN 2005E separately from other SN (Ib+Ic) because of their potentially distinct progenitor population.

We exclude SN IIn imposters (e.g., Van Dyk et al. 2000; Maund et al. 2006), a group which includes SN 1997bs, SN 1999bw, SN 2000ch, and SN 2001ac.

## 3.3. Classification of SN as Type IIb

While spectra taken over several epochs are necessary to observe the spectroscopic transition that defines SN IIb, such follow up is not always available. Fortunately, the spectra of Type IIb SN similar to SN 1993J are sufficiently distinctive that cross correlation with spectroscopic templates (e.g., the "Supernova Identification code" (Blondin & Tonry 2007)), has been able to identify substantial numbers of explosions as Type IIb from

a single spectrum. Although classifications based on a single spectrum may overlook examples of SN IIb, the Type IIb explosions they do identify should be reliable.

## 3.4. Classification of SN as Type Ib/c SN

The Asiago catalog entries sometimes have less information than the IAU Circulars and published papers. For example, SN 1997dq and SN 1997ef were listed in the Asiago catalog (as of November 2010) as "Type Ib/c" while Matheson et al. 2001 and Mazzali et al. 2004 identified them as SN Ic-BL. Motivated by these examples, we searched the circulars to see whether additional information was available. Despite making note of the presence or absence of helium more than ten days after the explosion, some authors report a Type Ib/c classification. These authors may feel that a SN Ib/c classification was sufficiently precise while, in other cases, they may have wanted to emphasize peculiar spectroscopic characteristics. An example is SN 2003A which was classified as a Type Ib/c by Filippenko & Chornock 2003 who noted that "[w]eak He I absorption lines are visible, but the overall spectrum resembles that of type-Ic supernovae."

Classifications by the Nearby Supernova Factory (Aldering et al. 2002; Wood-Vasey et al. 2004) reported in circulars include an unusually high percentage of Type Ib/c. The high fraction of SN Ib/c reported by the Nearby Supernova Factory survey is hard for us to assess without being able to see the spectra or use impartial classification techniques. We have therefore excluded SN discovered by the Nearby Supernova Factory from our statistical sample.

#### 3.5. Galaxy-Impartial and Targeted SN Surveys

We measure the host galaxy properties of SN discovered by both targeted surveys, which aristocratically discover almost all their SN in luminous galaxies, as well as galaxy-impartial surveys, which democratically scan swaths of sky without special attention to specific galaxies. Galaxy-impartial surveys generally employ larger telescopes (e.g., the SDSS 2.5m; the PTF 1.2m) than targeted surveys (e.g., the KAIT 0.76m), have fainter limiting magnitudes, and image much greater numbers of low-mass galaxies. The SN harvested by galaxy-impartial surveys are found in host galaxies that are not apparently bright or nearby (and are not in bright galaxy catalogs). For example, in our sample, 31% (40/130) of galaxy-impartial SN but only 3.4% (13/385) of targeted SN have host galaxy masses smaller than  $10^9 M_{\odot}$ .

### 3.6. Identifying Galaxy-Impartial Discoveries

We used the Discoverer column from the IAU classification<sup>8</sup> to determine the provenance of each SN. There are relatively few galaxy-impartial discovery teams, because discovering substantial numbers of SN by impartially scanning the sky requires significant dedicated observing time and investment in data processing. Any SN whose discovery team we did not identify as part of a galaxy-impartial search effort, including amateur discoveries, was considered a targeted discovery.

Surveys that we considered galaxy-impartial: Catalina Real-Time Sky Survey and Siding Spring Survey

## 3.7. Luminosity Functions, Light Curves, and Detection

Any type-dependent luminosity differences which influence the relative visibility of the SN types are a potential concern, because SN surveys may image different potential host galaxy populations at increasing redshift or with varying depth. For example, Leaman et al. 2011 report a Malmquist effect among the galaxies targeted by LOSS where more distant galaxies are, on average, more luminous. Detection efficiencies that depend on redshift and type could result in false correlations between host galaxy properties and SN type.

Table 4 shows the mean peak absolute magnitudes (before correction for host galaxy extinction) of the corecollapse SN species studied by Li et al. 2011b (LOSS) and Drout et al. 2010 (Palomar 60"). Drout et al. 2010 found that SN Ic-BL are intrinsically brighter explosions than normal Type Ic explosions. Besides SN Ic-BL, there is no strong or unanimous support for differences among the SN types. Although Li et al. 2011b found some evidence that SN Ib and SN Ic have different mean intrinsic luminosities, Drout et al. 2010 did not find a similar indication.

Modest differences among the mean luminosities of SN species do not necessarily correspond to strong differences among detection efficiencies, given redshift limits and survey cadence. Intrinsic SN luminosities vary by at least several magnitudes, even among SN of the same spectroscopic type. Li et al. 2011b found, for example, that the SN (Ib+Ic) luminosity function has a standard deviation of 1.24 mag and that the SN II luminosity function has a standard deviation of 1.37 mag.

## 3.7.1. Redshift Upper Limits for Targeted and Galaxy-Impartial Samples

To avoid misleading correlations introduced by the sample selection, we exclude SN discovered at redshifts where these SN surveys could only detect SN Ib, SN Ic, or SN II if they were brighter than average. Li et al. 2011b reported the mean peak luminosities of SN (Ib+Ic),

-16.09  $\pm$  0.23 mag, and SN II, -16.05  $\pm$  0.15 mag, discovered by LOSS. While LOSS survey observations are taken without a filter, the response function peaks in the R-band (Li et al. 2011b). For LOSS, which contributes 42% of our targeted sample, Leaman et al. 2011 find a median limiting magnitude of 18.8  $\pm$  0.5, corresponding to a detection limit of z=0.023 for SN (Ib+Ic) and SN II. We use this redshift as the upper limit for our targeted SN sample. Table 3 presents the median redshifts for each SN type.

Dilday et al. 2010 report a  $\sim$ 21.5 mag r'-band detection limit for the SDSS-II survey, which accounts for 33% of the galaxy-impartial sample. For our sample of galaxy-impartial discoveries, the redshift upper limit is z=0.08, corresponding to the SDSS-II detection limit. The PTF, accounting for 32% of galaxy-impartial SN, has a limiting R-band magnitude of  $\sim$ 20.8 mag which corresponds to an upper detection limit of z=0.056.

Varying the upper redshift limit for galaxy-impartial and targeted SN discoveries (e.g., from z=0.023 to z=0.02 or z=0.06) does not alter the type-dependent trends we find.

#### 3.8. Galaxy-Impartial SN Discoveries as a Test

Except for cosmic evolution, low-redshift galaxy-impartial surveys image the same galaxy populations at increasing redshift. Therefore, the SN populations that explode within the field of view of galaxy-impartial surveys at each redshift to z < 0.15 should be unvarying, with constant fractions of each SN type, so the mix of SN types as a function of redshift reflects the efficiency of the survey for each type at each redshift.

Figure 1 plots the cumulative redshift distributions of core-collapse SN reported to the IAU by galaxy-impartial surveys with z < 0.15. We extend the redshift upper limit beyond the z = 0.08 galaxy-impartial limit to compile a larger sample of SN discoveries. The samples of some SN species are modest, but this plot provides no suggestion that these surveys are, in the aggregate, more or less sensitive to the explosions of SN II, SN IIb, SN IIn, SN Ib, SN Ic, and SN Ic-BL with increasing redshift. Besides their targeting patterns, galaxy-impartial and targeted surveys are generally alike, so a reasonable assumption is that any type-dependent luminosity differences also do not strongly affect our targeted SN sample.

## 3.9. Approximately Consistent Efficiency and Combination of Samples

We have found some evidence that, for each galaxy imaged within the redshift limit, the probability of detecting a SN is independent of the spectroscopic type of the SN. This implies that differences among the host properties of detected SN largely reflect the environmental preferences of each SN type, not primarily type-dependent

TABLE 4
SN LUMINOSITY FUNCTIONS

| Survey                  | II                | IIn               | IIb               | Ib                | Ic                | Ic-BL           | Ib+Ic             |
|-------------------------|-------------------|-------------------|-------------------|-------------------|-------------------|-----------------|-------------------|
| LOSS (Li et al. 2011b)  | $-16.05 \pm 0.17$ | $-16.86 \pm 0.59$ | $-16.65 \pm 0.40$ | $-17.01 \pm 0.17$ | $-16.04 \pm 0.31$ |                 | $-16.09 \pm 0.23$ |
| P60 (Drout et al. 2010) |                   |                   |                   | $-17.0 \pm 0.7$   | $-17.4 \pm 0.4$   | $-18.3 \pm 0.6$ |                   |

NOTE. — Estimates of the mean luminosities of the SN types by Li et al. 2011b and Drout et al. 2010. The LOSS and the P60 samples, respectively, are constructed differently, but differences between the mean luminosities of the SN species should be approximately consistent for these surveys. Li et al. 2011b favor a much larger difference between SN Ib and SN Ic luminosities than that found by Drout et al. 2010. SN Ic-BL may be more intrinsically luminous than SN Ic. Luminosities above are before correction for extinction, for studying SN detection efficiency.

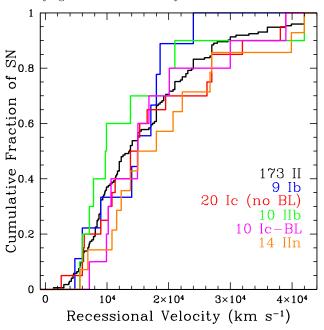

Fig. 1.— Recessional velocities of SN discovered by galaxy-impartial surveys. To increase sample size, the plot includes discoveries to z=0.15, a higher upper limit than the z=0.08 galaxy-impartial sample limit. Except for cosmic evolution, low-redshift galaxy- impartial surveys image the same galaxy populations at increasing redshift. The samples of some SN species are modest, but this plot provides no suggestion that these surveys are, in the aggregate, more or less sensitive to the explosions of SN II, SN IIb, SN IIn, SN Ib, SN Ic, and SN Ic-BL with increasing redshift.

luminosity selection effects. We can therefore combine the galaxy-impartial and targeted samples with reasonable confidence before we compare host galaxy properties.

#### 4. METHODS

## 4.1. SDSS Imaging Processing

The WCS provided in SDSS DR8 frame\*.fits headers is a TAN approximation to the asTrans\*.fits full astrometric solution and has subpixel accuracy (private communication; M. Blanton), an improvement over the astrometric solution provided in DR7 fpC\*.fit headers. We used SWarp (Bertin et al. 2002) to register and resample SDSS images of each host galaxy to a common pixel grid and coadded SDSS images in the u'g'r'i'z' bands. The SDSS DR8 frame\*.fits images also feature an improved background subtraction (in comparison to DR7 fpC\*.fit images). The DR8 background level is estimated from a spline fit across consecutive, adjacent frames from each drift scan, after masking objects in each image.

## 4.2. Galaxy Photometry and Stellar Mass

Host galaxy images were used to measure the color of the stellar population near the site of each SN, estimate each host's stellar mass, a proxy for chemical enrichment (e.g., Tremonti et al. 2004), and compute the deprojected host offsets of SN and SDSS spectroscopic fibers. The SExtractor measurement MAG\_AUTO, corresponding to the flux within 2.5 Kron (1980) radii, was used to estimate host galaxy stellar mass-to-light ratio (M/L)through fits with spectral energy distributions (SEDs) from PEGASE2 (Fioc & Rocca-Volmerange 1997, 1999) stellar population synthesis models using the appropriate SDSS instrumental response function. An estimate of the stellar mass was then computed:  $M = M/L \times L$  where L is the galaxy's absolute luminosity. See Kelly et al. 2010 for a detailed description of the star formation histories used.

We then estimated the host galaxy's color near the SN location using two techniques. The first and more simple method was to extract the u'q'r'i'z' flux inside of a circular aperture with 300 pc radius centered on the SN location, after subtracting the median of the peripheral background regions. While this technique is straightforward, apertures centered at the sites of SN at large host offsets or found in low-luminosity hosts had low S/N, especially in the u' and z' bands. The primary intent of the second method was to obtain higher S/N u'-band flux measurements near the sites of SN, in particular near the sites of the SN with faint hosts. To identify g'-band pixels with S/N > 1, we searched the SExtractor segmentation map generated with settings DETECT\_THRESH=1 and DETECT\_MINAREA=10 (minimum of 10 contiguous pixels with S/N > 1). The 20 pixels closest to the SN location contained in the g'-band segmentation maps define the aperture for measurements of u'-z' color and u'-band surface brightness. We correct for Galactic reddening using the Schlegel et al. 1998 dust maps.

We note that each K-corrected magnitude which we computed using KCORRECT (v. 4.13) (Blanton & Roweis 2007) reflects the shape of the best-fit SED and therefore the full set of u'g'r'i'z' measurements. Consequently, even if the u' and z' fluxes are noisy, the K-corrected u'-z' color is still a useful indicator of the shape of the SED that best fits less noisy g'r'i' fluxes.

## 4.3. Selecting SDSS Spectroscopic Fibers

To identify SDSS fibers that coincide with a host galaxy, we searched inside a catalog available online from an MPA-JHU collaboration  $^9$  for fibers that fell within an

<sup>9</sup> http://www.mpa-garching.mpg.de/SDSS/DR8/

aperture with radius (1.65/z)" placed on the host center and with redshifts that agree with that of the SN. For an object in the Hubble flow, this angle corresponds to a physical distance of approximately 34 kpc. At z=0.03, for example, this radius subtends a 55" angle. If the g'-band SExtractor segmentation map ID at the fiber location was the same as the ID of the SN host galaxy, the fiber was considered a match to the galaxy after a visual check. The deprojected normalized offset of the fiber was then calculated by computing the offset at each pixel in the 3" fiber aperture and averaging these offsets weighted by each pixel's g'-band counts.

## 4.4. AGN Activity

The hard ionizing continuum of AGN emission affects the relative strengths of the strong optical nebular emission lines, making a nuclear spectrum a useful indicator of activity. The patterns associated with AGN activity are significantly degenerate with variation in oxygen abundance, however, so AGN contamination precludes metallicity measurements.

We use the classifications of fiber spectra as star forming, low S/N star forming, composite, AGN, or low S/N AGN made available by the MPA-JHU group following Brinchmann et al. 2004. That analysis uses each spectrum's position on the Baldwin et al. 1981 (hereafter BPT) diagram of [O III]  $\lambda 5007/{\rm H}\beta$  and [N II]  $\lambda 6584/{\rm H}\alpha$  line ratios.

### 4.5. Extinction Estimated from Balmer Ratios

From the fiber spectra (closest in deprojected offset to the SN sites), we estimate host galaxy reddening  $A_V$  using the Balmer decrement ( $\text{H}\alpha/\text{H}\beta$ ), assuming the  $R_V$ =3.1 Cardelli et al. 1989 extinction law. Following Osterbrock 1989, we assume a Case B recombination ratio of 2.85 when spectra are classified as star forming or low S/N star forming and a ratio of 3.1 when spectra are classified as composite, AGN, or low S/N AGN.

## 4.6. Metallicity and Specific SFR Measurements

Our analysis uses both (a) abundances and specific star formation rate estimates available from the MPA-JHU collaboration for SDSS fiber spectra and (b) abundances we compute using the Pettini & Pagel 2004 metallicity calibration. We only use galaxies with S/N>3 H $\beta$ , H $\alpha$ , [N II]  $\lambda6584$ , and [O III]  $\lambda5007$ , as designated by the MPA-JHU analysis. For abundance measurements, we only analyze spectra classified as star forming. For specific SFR estimates, we use star forming, composite, and AGN spectra.

### 4.6.1. MPA-JHU Metallicity and Specific SFR

To extract an oxygen abundance and specific SFR from a spectrum, the MPA-JHU collaboration first uses Charlot & Longhetti 2001 stellar population synthesis and photoionization models to calculate an extensive library of line strengths spanning potential effective gas parameters including gas density, temperature, and ionization as well as the dust-to-metal ratio. Then galaxy [O II], H $\beta$ , [O III], H $\alpha$ , [N II], and [S II] optical nebular emission lines are fit simultaneously with the library and used to compute metallicity and specific SFR likelihood distributions. Here we use the median of these

distributions as the oxygen abundance and specific SFR estimates.

When AGN contaminate emission lines, metallicity estimates are not possible but the MPA-JHU group uses the strength of the 4000Å break [see Figure 11 of Brinchmann et al. 2004] and the ratio  ${\rm H}\alpha/{\rm H}\beta$  to estimate the specific SFR<sup>10</sup>.

## 4.6.2. Pettini and Pagel Metallicity

Since we have no prejudice about which emission-line method is most correct, we have also computed abundances using the Pettini & Pagel 2004 (hereafter PP04) prescription. This is based on the relative line strengths of H $\beta$ , H $\alpha$ , [N II]  $\lambda6584$ , and [O III]  $\lambda5007$ , after correcting for dust emission. The PP04 indicator relies on lines relatively close in wavelength, reducing its sensitivity to uncertainty in the extinction correction and does not require the [O II]  $\lambda3727$  line, which falls beyond the blue sensitivity of the SDSS spectrograph for objects at z<0.02.

Our measurements trace the Kewley & Ellison 2008 PP04 mass-metallicity relation of SDSS galaxies when stellar mass is plotted against 'central' metallicity for galaxies in the Hubble flow (z>0.005). Fibers were considered 'central' if their deprojected offset was less than 0.35 the half-light radius or were closer than 2 kpc to the galaxy center.

### 4.7. Comparison of Host Abundance Proxies

Oxygen abundances measured from fibers centered on the host galaxy nucleus are, on average, only 0.01 dex (T04) greater than the abundance inferred from the stellar mass with the Tremonti et al. 2004 *M-Z* relation, with a scatter of 0.14 dex. If we instead select fibers closest in host offset to SN explosion sites, spectroscopic abundances are 0.053 dex (T04) less than abundances estimated from stellar masses with a scatter of 0.16 dex.

#### 5. STATISTICAL METHOD

## 5.1. Kolmogorov-Smirnov Statistic

In the following sections, we test the null hypothesis that two samples are drawn from a single underlying distribution using the Kolmogorov-Smirnov (KS) test. The KS test statistic is defined as  $D = \sup_x |F_1(x) - F_2(x)|$ , the maximum difference between the samples' cumulative distribution functions, where  $F_n(x) = \frac{1}{n} \sum_{i=1}^n I_{X_i \leq x}$ . The KS distribution is the distribution of the test statistic D, given the null hypothesis that two distributions are identical. The p-value is the probability of observing a value of the test statistic, D, more extreme than the observed value of D given the null hypothesis that the two samples are drawn from a single underlying distribution. Low p-values (< 5%) are significant evidence that the underlying distributions are distinct.

When two independent samples are drawn from the same distribution, there is, by definition, a 5% random chance of obtaining a p-value less than 5%. If we were to make, for example, twenty comparisons among samples drawn from identical distributions, one misleading p<5%

<sup>&</sup>lt;sup>10</sup> http://www.mpa-garching.mpg.de/SDSS/DR7/sfrs.html

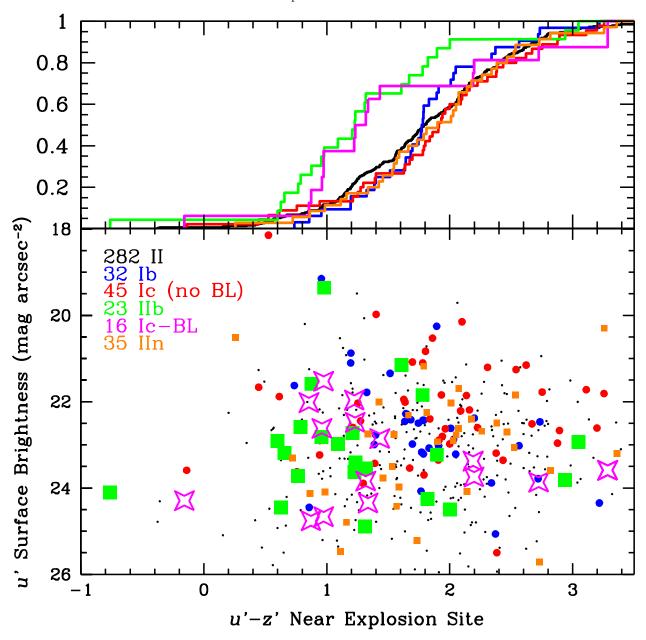

Fig. 2.— Host galaxy u'-z' color versus u' surface brightness near SN location. The top panel plots the fraction of SN of each type with environments bluer than the horizontal axis coordinate. SN IIb environments are bluer than SN Ib, SN Ic, and SN II environments (p=0.2%, 0.5%, and 0.3%, respectively), and SN Ic-BL environments are bluer than those of SN Ib, SN Ic, and SN II (p=2.3%, 2.1%, and 1.7%, respectively). SN Ib and SN Ic explode in regions with higher u'-band surface brightness than do SN II (p=2.4% and 0.3%, respectively), and SN Ic sites have higher u'-band surface brightnesses than SN Ic-BL locations (0.7%). The aperture is the 20 host pixels with S/N > 1 in g' band nearest the SN location.

difference would occur by chance on average. The number of independent comparisons we make in this paper should therefore be taken into account when comparisons yield p-values of modest significance (p  $\sim 5\%$ ). We note that the host properties we measure are correlated (e.g., host color and metallicity), so independent comparisons are fewer than the total number of comparisons.

### 6. RESULTS

Instead of placing the numerical values of all statistical Kolmogorov-Smirnov (KS) tests in the following descriptions of results, we instead list many of them in Table 5, which includes comparisons for all types, and Table 6, which includes comparisons for SN IIb and SN Ic-BL, restricted to only targeted and only galaxy-impartial samples. Table 7 contains the measurements of the SN host galaxies.

## 6.1. Host Color and u' Surface Brightness Near Explosion Site

As can be seen in Figure 2, SN IIb and SN Ic-BL erupt in exceptionally blue environments, while high u'-band surface brightness is typical of SN Ib and SN Ic sites. This plot shows u'-z' color versus u'-band surface brightness, measured inside an aperture consisting of the 20 pixels closest to the SN site with g'-band S/N > 1. The u'-z' color near the site of SN 2006aj, the SN-

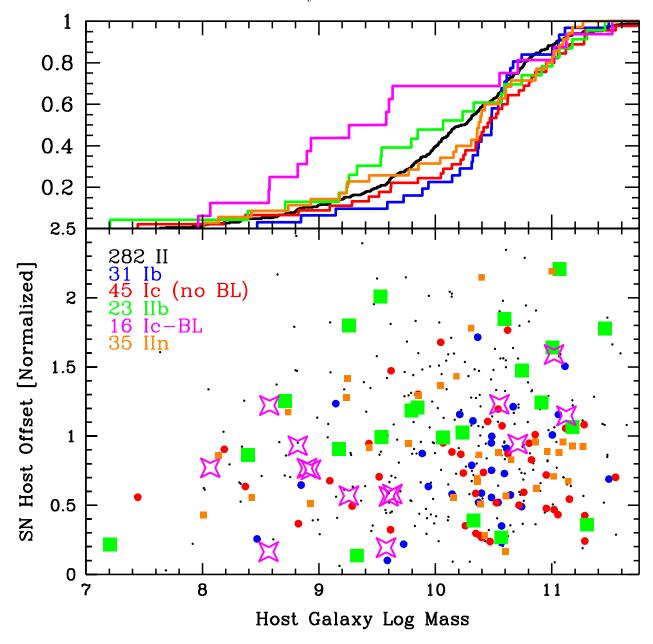

Fig. 3.— Stellar masses of host galaxies versus SN host offset, deprojected and normalized by host g'-band half-light radius. The top panel plots the fraction of each SN type with hosts less massive than the horizontal axis coordinate. SN Ic-BL are found in significantly less massive galaxies than are the SN Ib, SN Ic, or SN II (p=7.6%, 4.4%, and 20%, respectively). Host galaxy stellar masses are estimated from PEGASE fits to u'g'r'i'z' host magnitudes. A two-sample KS test finds evidence (p=5.1%) that SN IIb explode at larger host offsets than SN Ib. SN Ic explode closer to their host centers than SN II (p=0.2%).

LGRB in our sample, was 0.88 mag.

### 6.2. Host Stellar Mass and SN Host Offsets

Figure 3 helps to explain the exceptionally blue  $u^{\prime}$ - $z^{\prime}$  color of SN IIb and SN Ic-BL sites and the high  $u^{\prime}$ -band surface brightnesses near SN Ib and Ic sites. At one set of extremes, SN Ic-BL have generally low mass hosts, while SN IIb explode at larger offsets when they occur in galaxies of large masses. At another extreme, SN Ib and especially SN Ic more often occur inside the  $g^{\prime}$ -band half-light radius of massive galaxies, sites expected to have redder color and high surface brightness. SN II sites are indifferent, showing no evident preference in color or surface brightness.

Host galaxy mass is a moderately precise ( $\sim 0.1$  dex) proxy for chemical abundance (e.g., Tremonti et al. 2004) which does not suffer from the AGN selection effects. The hosts of SN (Ib+Ic), excluding SN Ic-BL, are more massive than SN II hosts.

The host stellar mass of SN 2006aj, the only SN-LGRB in our sample, was  $8.0 \times 10^{10} M_{\odot}$ . We find with p=13% that the SN IIn offset distribution is consistent with the SN II host offset distribution.

## 6.3. Oxygen Abundance Measurements Closest to SN Positions

To probe the metallicities of the core-collapse hosts, we measure oxygen abundance from the fiber spectrum with

Note. — P-values from Kolmogorov-Smirnov two-sample comparisons that include both targeted SN and galaxy-impartial SN discoveries. The two rows below "T04/PP04" show oxygen abundance statistics computed from spectra whose host offsets are within 3 kpc of the SN host offset.

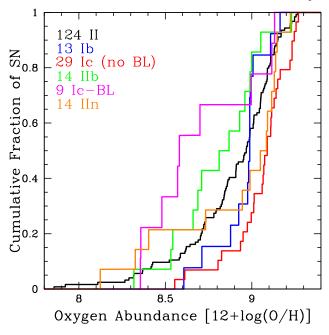

FIG. 4.— Host oxygen abundance measured from SDSS 3" fiber spectrum with host radial offset most similar to that of SN explosion site. While Tremonti et al. 2004 spectroscopic abundances are plotted, we also measure abundances using the Pettini & Pagel 2004 calibration. Even when we consider only SN discovered by galaxy-impartial surveys, we find a statistically significant difference between the SN Ic-BL and the SN Ic host abundance distributions (p=0.7%/0.7%, respectively for the T04/PP04 calibrations). When we consider only SN discovered by targeted surveys, we find a statistically significant difference between the SN IIb and the SN Ib host abundance distributions (p=4.7%/0.6%, respectively for the T04/PP04 calibrations).

deprojected offset most similar to the SN offset. SDSS fiber spectra generally target the central regions of host galaxies, with an average host offset in our sample of  $0.45 \times r_{half-light}$ . The low metallicities shown in Figure 4 for SN Ic-BL and SN IIb hosts and high metallicities for SN Ic hosts are consistent with the patterns we see among the species' colors near explosion sites, host offsets, and host masses.

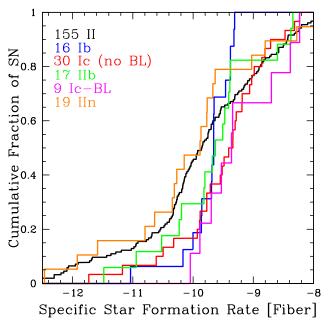

FIG. 5.— Host specific SFR estimated from SDSS 3" fiber spectrum with host radial offset most similar to that of SN explosion site. The sequence of the spectroscopic classes, arranged in order of the loss of the progenitor's outer hydrogen and helium envelopes (i.e., SN II, SN IIb, SN Ib, SN Ic), exhibit increasing average host galaxy specific SFR (SFR  $\rm M_{\odot}^{-1}~yr^{-1})$ , measured from SDSS fiber spectra. SN Ic hosts have greater specific SFR than SN Ib hosts (p=2.7%), while SN Ib hosts have greater specific SFR than SN II hosts (6.5%). SN Ic-BL hosts have greater specific SFR than SN II hosts (5.9%). SDSS fibers largely sample light within the the host galaxy half-light radius and are often centered on the host galaxy nucleus.

## 6.3.1. Every Abundance Measurement

For galaxy-impartial discoveries, SN Ic-BL hosts (n=4) follow a significantly more metal-poor distribution than the hosts of normal SN Ic (n=5; p=0.7%/0.7% for T04/PP04 calibrations). Among the hosts of targeted discoveries, host galaxies of SN IIb (n=13) follow a significantly more metal-poor distribution than hosts of SN Ib (n=10; p=4.7%/0.6%).

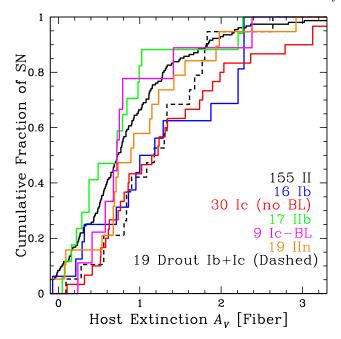

FIG. 6.— Host extinction estimated from 3" SDSS fiber spectrum with host radial offset most similar to that of SN explosion site. There is significant evidence that SN IIb and SN II hosts have less internal extinction than SN (Ib+Ic) host galaxies (p=3.0% and 1.6%, respectively). The Drout et al. 2010 SN (Ib+Ic)  $A_V$  extinction values estimated along the line of sight to the SN from light curve color and shape are consistent with the values we measure, although the spectroscopic fibers are largely not positioned at the SN site.

 ${\bf TABLE~6} \\ {\bf KS~p\text{-}values~for~Different~Samples}$ 

|                 | Sample    | IIb vs. Ib         | Ic-BL vs. Ic       |

|                 | Impartial | 62% (6, 7)         | 60% (9, 9)         |

NOTE. — P-values and sample sizes from Kolmogorov-Smirnov two-sample comparisons that include targeted SN discoveries, galaxy-impartial SN discoveries, or both. The difference between the metallicity distributions of the hosts of Type Ic-BL and Type Ic SN is statistically even when including only SN discovered by galaxy-impartial hosts. The differences between the SN Ib and SN Ilb host galaxy u'z' color distributions as well as host galaxy metallicities are statistically significant when including only SN discovered by targeted surveys.

The SN II host abundance distribution is more metalpoor than that of the SN Ic hosts, but a selection effect may inflate any difference. A higher fraction of SN II  $(21\pm3\%~(42/196))$  than SN (Ib+Ic) host spectra  $(9\pm4\%~(4/47))$  have the emission line ratios of AGN (see Tables 1 and 2), which makes spectra unusable for abundance analysis. AGN occur primarily in massive, metal-rich galaxies ( $M > 10^{10} M_{\odot}$ ; Kauffmann et al. 2003), so rejecting AGN spectra removes a higher fraction of metal-rich SN II hosts than of SN Ib/c hosts. A host galaxy with mass  $10^{10.5} M_{\odot}$ , typical of an AGN host, will have an oxygen abundance of  $\sim 9$  dex (T04) and  $\sim 8.75$  dex (PP04) (e.g., Tremonti et al. 2004).

SN IIn hosts follow a similar distribution to that of the entire SN II sample (p=37%/55%).

#### 6.3.2. When Fiber and SN Host Offsets Are Similar

Most galaxies have metallicity gradients, with abundance declining away from the galaxy center. Van Zee et al. 1998 found, for example, a mean radial abundance gradient of -0.052 dex kpc $^{-1}$  for a sample of 11 NGC host galaxies. To assemble improved proxies for metallicity at the SN location, we selected fibers whose deprojected host offset (away from the galaxy center) was within 3 kpc of that of a SN.

Among these fibers, the SN Ic-BL host spectra are significantly more metal-poor than both the SN Ib and SN Ic spectra. More qualified evidence exists that SN Ic spectra are more metal-rich than SN Ib spectra (p=2.4%/8.5% for T04/PP04). Without correcting for the effect of AGN activity, the SN II host fibers (with similar host offset) are significantly less metal-rich than that of SN Ic host fibers.

Median offset differences between the SDSS fiber and SN location in right panel (in kpc): SN Ib (1.02), SN Ic (1.32), SN Ic-BL (1.56), SN II (1.11), SN IIb (1.66).

# 6.4. Host Specific Star Formation Rate from Fiber Spectra

SDSS spectra provide an estimate of the specific SFR (SFR  ${\rm M}_{\odot}^{-1}~{\rm yr}^{-1}$ ) within the aperture of the fiber, which generally targets the host galaxy within the g'-band half-light radius. As can be seen in Figure 5, there is a progression of increasing specific SFR from SN II to SN Ib to SN Ic host spectra. SN Ic-BL host spectra also have significantly greater specific SFR than SN II host spectra.

Using visual inspection, we identified fibers that target the nuclei of host galaxies (to z < 0.02). These spectra yield significant evidence that the nuclei of SN (Ib+Ic) host galaxies have greater specific star formation rates than those of SN II host galaxies (p=3.5%). This strong central star formation among SN (Ib+Ic) hosts may overwhelm AGN-patterned emission, explaining the relatively low AGN fraction among SN (Ib+Ic) host galaxies.

### 6.5. Extinction Inferred from Spectra

Although SN Ic hosts have stronger specific SFR within the half-light radius, the region where most SN Ic explode, the sites of SN Ic are not bluer than those of SN II (see Figure 2). Figure 6 shows that the high extinction of SN (Ib+Ic) host galaxies, measured from host spectra, may redden ongoing star formation in SN Ic host galaxies.

The host galaxies of SN IIb have less extinction than SN (Ib+Ic) host galaxies. The average extinction difference between SN (Ib+Ic) and SN IIb hosts is  $A_V \sim 0.5$  mag, a u'-z' reddening of  $\sim 0.6$  mag. The approximately

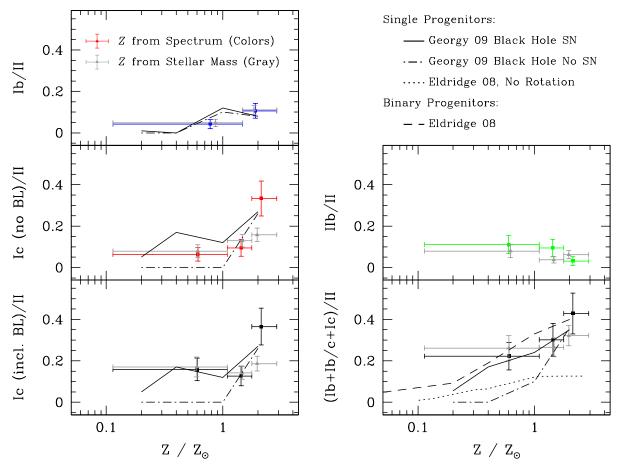

Fig. 7.— Ratio of stripped-envelope SN to SN II versus oxygen abundance (T04 calibration). The comparatively high fraction of SN (Ib+Ib/c+Ic) to SN II at subsolar metallicity in the right lower panel favors contributions from a binary progenitor population or explosions even after collapse to a black hole. Color points correspond to spectroscopic metallicity measurements, and gray points correspond to metallicities estimated from stellar masses using the Tremonti et al. 2004 mass-metallicity relation. The comparatively high fraction of SN II host fiber spectra with contamination from AGN activity (present only in massive, metal-rich galaxies) excludes a considerable fraction of metal-rich SN II host galaxies, inflating the apparent fraction of stripped-envelope SN in metal-rich galaxies (color points). Indeed, the stripped-envelope fraction is smaller using metallicities estimated from host galaxy stellar masses (gray) which do not suffer from an AGN selection effect. Dashed line is Eldridge et al. 2008 prediction for binary progenitors; dotted line is Eldridge et al. 2008 prediction for non-rotating single progenitors; and solid and dash-dot lines are Georgy et al. 2009 predictions for single, rotating progenitors (where a minimum helium envelope of  $0.6~\rm M_{\odot}$  separates SN Ib from SN Ic progenitors). Whether core collapse to a black hole can yield a SN explosion is not clear (e.g., Fryer et al. 1999), especially if high angular momentum does not support an accretion disk (Woosley et al. 1993). The Georgy et al. 2009 solid line prediction is where core collapse to a black hole yields no SN. Vertical error bars reflect Poisson statistics while horizontal bars reflect the range of metallicities in each bin with the position of the vertical bar corresponding to the mean Z in the bin. Here  $Z_{\odot} = 8.86$  from Delahaye et al.

similar internal extinctions of SN II and SN IIb hosts, however, suggest that the stellar populations near SN IIb likely are intrinsically bluer than those near SN II sites.

SN (Ib+Ic) host reddening is consistent (p=45%) with that estimated along the line-of-sight to 19 SN (Ib+Ic) from their light curve colors by Drout et al. 2010 using an empirical model of SN Ib/c photometric color evolution. Comparison between the Drout et al. 2010 sample and the SN II host  $A_V$  distribution yields p=2.4%. Here we plot only the Drout et al. 2010 Gold and Silver SN. There is a median  $A_V \sim 1.2$  mag extinction through SN (Ib+Ic) host fiber apertures  $(E(B-V) \sim 0.4$  mag).

## 7. RELATIVE FREQUENCIES OF CORE-COLLAPSE SN AS A FUNCTION OF METALLICITY

Figure 7 plots the ratio of stripped-envelope SN (including SN IIb) to SN II with increasing host galaxy oxygen abundance. Vertical error bars show the Poisson

uncertainties, while horizontal bars indicate the range of metallicities in each bin. The color points are calculated from successful *spectroscopic* metallicity measurements, while the gray points are estimated using *stellar mass* as a metallicity proxy, applying the Tremonti et al. 2004 mass-metallicity relation.

AGN emission, present disproportionately in SN II host spectra, is found primarily in high-mass, high-metallicity galaxies. This selection effect misleadingly inflates the apparent ratio SN (Ib+Ic) / SN II (color points) in the highest metallicity bin. Indeed, the ratio at high metallicity calculated instead using stellar masses as a proxy (which has no similar selection effect) is significantly lower (gray points). Earlier efforts using SDSS fiber spectra (i.e., Prieto et al. 2008), which also exclude AGN-contaminated spectra, have not noted this strong selection effect at high metallicity.

We compare relative rates to the model predictions for single, rotating progenitors (Georgy et al. 2009),

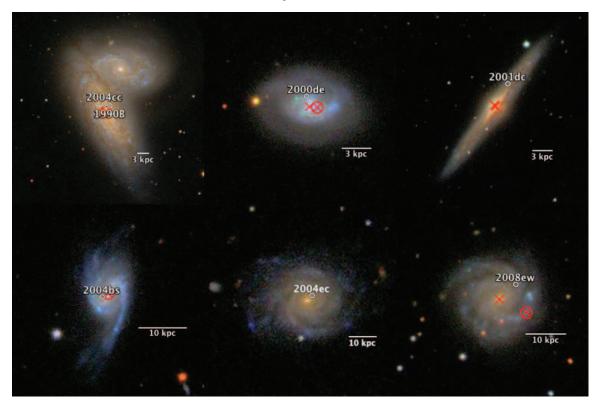

Fig. 8.— SDSS color composite images of 6 SN Ib, SN Ic, and SN II host galaxies in our sample. These include: SN 1990B (Ic), SN 2004cc (Ic), SN 2000de (Ib), SN 2001dc (IIP), SN 2004bs (Ib), SN 2004ec (IIn), and SN 2008ew (Ic). Red cross hatches show SDSS fibers positions yielding oxygen abundance measurements. An additional red circle marks fibers whose host offsets are within 3 kpc of the SN offset.

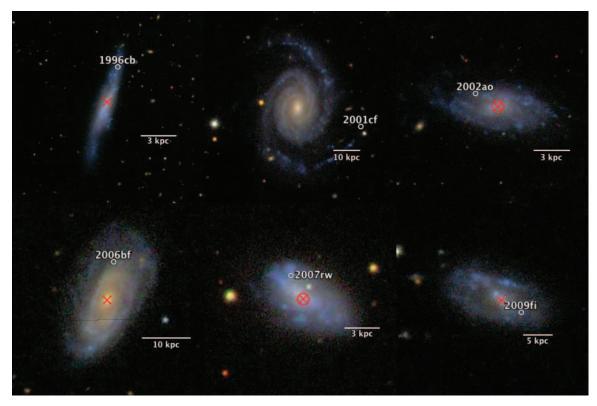

Fig. 9.— SDSS color composite images of 6 SN IIb in our sample. Their local environments are substantially bluer than those of SN Ib, SN Ic, and SN II. Red cross hatches show SDSS fibers positions yielding oxygen abundance measurements. An additional red circle marks fibers whose host offsets are within 3 kpc of the SN offset.

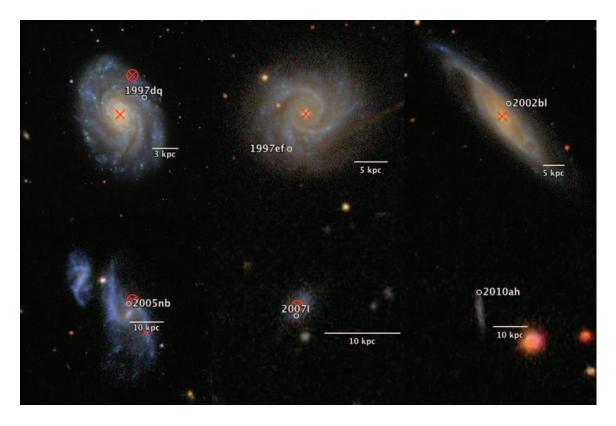

FIG. 10.— SDSS color composite images of 6 SN Ic-BL in our sample. SN Ic-BL in our sample occurred preferentially in lower-mass, low-metallicity host galaxies. Red cross hatches show SDSS fibers positions yielding oxygen abundance measurements. An additional red circle marks fibers whose host offsets are within 3 kpc of the SN offset.

single, non-rotating progenitors (Eldridge et al. 2008), and binary progenitors (Eldridge et al. 2008). Plotted Georgy et al. 2009 predictions were made with the assumption that a minimum helium envelope of 0.6  $\rm M_{\odot}$  separates the progenitors of SN Ib and SN Ic. Because core collapse to a black hole may not yield a SN explosion (e.g., Fryer et al. 1999), especially if high angular momentum does not support an accretion disk (Woosley et al. 1993), Georgy et al. 2009 calculated predictions where viable SN occur after core collapse to (a) only neutron stars and (b) neutron stars and black holes. These predictions adopted 2.7  $\rm M_{\odot}$  as the maximum mass of neutron star (Shapiro & Teukolsky 1983) and use the Hirschi et al. 2005 relation between neutron star mass and the mass of the carbon-oxygen core.

Model predictions are parameterized by  $Z/Z_{\odot}$ , requiring us to subtract the solar value from  $12 + \log(O/H)$  estimates for each host galaxy to compute  $\log(Z/Z_{\odot})$ . The value of the solar metallicity is, however, not well constrained. Atmospheric modeling favors lower solar values (e.g.,  $12 + \log(O/H) = 8.69$ ; Asplund et al. 2009) than helioseismic analyses (e.g.,  $12 + \log(O/H) = 8.86$ ; Delahaye et al. 2010). Here we use the helioseismic value of Delahaye et al. 2010.

Returning to our data, we note that the spectroscopic oxygen abundance measurements should, on average, be overestimates of the oxygen abundance at the SN site because the SDSS fibers are concentrated toward the inner regions of the galaxies. Likewise, abundances calculated from host masses and the Tremonti et al. 2004 M-Z relation should also be overestimates, because the Tremonti et al. 2004 relation is a fit to SDSS stellar masses and fiber metallicities.

The models for binary progenitors (Paczyński 1967; Podsiadlowski et al. 1992; Eldridge et al. 2008; Yoon et al. 2010; Claevs et al. 2011) in Figure 7 predict a higher fraction of stripped-envelope SN at low metallicities than do the single progenitor models (where core-collapse to a black hole does not yield a SN). This is because binary interaction can effectively strip away the outer envelopes of progenitors at low metallicities where wind-driven mass loss is not strong enough to expel the outer envelopes of most single massive stars (Eldridge et al. 2008; Smartt 2009; Yoon et al. 2010). Low metallicity stars that do lose their envelopes to winds have such large mass that their cores will collapse to a black hole. Given these model predictions, the comparatively high fraction of SN (Ib+Ib/c+Ic) to SN II at subsolar metallicity in the right lower panel favors contributions from a binary progenitor population or SN that accompany collapse to a black hole.

Smith et al. 2010b note that single star models use constant rates of wind-driven mass loss substantially greater than those observed, although episodic mass loss may speed loss of the outer envelopes. Lower wind-loss rates would imply a diminished fraction of single progenitors.

Splitting our sample in two at z=0.015, the same trends persist in both the low and high redshift subsamples, indicating that they do not result from luminosity-dependent selection effects.

#### 8. TESTS AND POTENTIAL SYSTEMATIC EFFECTS

8.1. Fiber Aperture Coverage

SDSS spectroscopic fiber apertures have a fixed radius of 1.5". At increasing redshift, this aperture radius corresponds to larger physical scales: 0.3 kpc at z=0.01; 0.6 kpc at z=0.02; and 1.17 kpc at z=0.04. For a sample of 11 NGC spiral galaxies, van Zee et al. 1998 found a mean radial abundance gradient of -0.052 dex kpc<sup>-1</sup>. While metallicity gradients vary among galaxies and have some dependence on, for example, host galaxy morphology (e.g., Kewley et al. 2006) and the metallicity calibration (e.g., Moustakas et al. 2010), we use this as a representative value.

Within the targeted sample (z < 0.023), nuclear spectroscopic fibers extend at most 0.68 kpc away from the host center, corresponding to systematic shifts of order only  $\sim 0.025$  dex. Galaxy-impartial SN discoveries (to z < 0.08) account for a significant fraction of only the SN Ic-BL sample. The difference between the median abundances for SN Ic-BL and SN Ic hosts is  $\sim 0.5$  dex, substantially greater than an aperture effect may yield.

## $8.2. \ Classification$

There may be variation among the classification practices of the different surveys that contribute to our samples. A concern is that surveys that monitor different host galaxy populations (e.g., galaxy-impartial and targeted) could have different classification practices, such as use of automated classification tools (e.g., SNID (Blondin & Tonry 2007)) or multi-epoch spectroscopic follow up. For instance, the helium lines that identify SN Ib often emerge only after a couple of weeks (e.g., Li et al. 2011b).

## 8.3. Fiber Targeting

The SDSS object detection algorithm mistakenly split many galaxies of large angular size into two or more components [see Fig. 9 of Blanton et al. 2005]. The SDSS targeting algorithm then placed fibers on these false components, sometimes at significant offset from the true galaxy center. The error rate of these algorithms could depend on galaxy morphology (e.g., irregularity or an interacting neighbor), and we checked whether the offsets of fiber measurements depend on SN type. However, we found no evidence of strong variation with SN type.

SDSS fibers often target the local maxima of galaxy light distributions, including host nuclei and bright HII regions. In our sample, fibers have mean offset of  $0.45 \times r_{half-light}$ , while matched fibers (where  $|r_{env}-r_{fiber}|<3~{\rm kpc}$ ) have mean offset of  $0.55 \times r_{half-light}$ . Therefore, fiber sites are highly likely to be more metal-rich on average than they would be if SDSS fibers sampled galaxy light distributions more democratically. However, the fibers' offset distribution does not vary strongly with SN type.

The lifetimes of HII regions may be shorter than the those of the progenitors (private communication; N. Smith), and the signal at the SN site may be too weak. Programs that take host spectra at the location of the SN (e.g., Anderson et al. 2010; Modjaz et al. 2011; Leloudas et al. 2011) may only extract a metallicity estimate when there is sufficient nebular emission through the slit. Any such S/N requirement could possibly act as a type-dependent selection effect. The SDSS targets bright nuclei or HII regions, moderating any such effect in our analysis.

#### 9. DISCUSSION

Our study of core-collapse host environments has revealed several statistically significant patterns. We have found that the u-z-z colors of SN IIb and SN Ic-BL (without an associated LGRB) environments are blue in comparison to those of other stripped-envelope SN environments. The host specific SFR (SFR  $M_{\odot}^{-1}$  yr $^{-1}$ ) is higher, on average, for types whose SN spectra indicate more complete loss of the progenitor's outer envelopes (i.e., SN Ib, SN Ic, SN Ic-BL). Spectroscopy also shows that SN Ic-BL host galaxies are more metal-poor than the hosts of normal SN Ic explosions, while SN IIb hosts also are more metal-poor and have less extinction, on average, than SN Ib or SN Ic host galaxies.

A surprising effect is that spectroscopic contamination by AGN is higher among SN II hosts than SN (Ib+Ic) hosts. This is important to the correct interpretation of host galaxy properties from SDSS spectroscopy.

This study is statistical, and we have shown only that samples are drawn from differing underlying distributions in our comparisons. The distinctions we present are consistent with even considerable variation among the environments of individual examples of each SN type.

## 9.1. Synthesizing Patterns

There are strong connections among the typedependent patterns in host galaxy photometry and spectroscopy:

- Host galaxies of SN Ic-BL generally have low mass and high specific SFR, helping to explain the blue colors at broad-lined SN Ic explosion sites. SN IIb typically are found beyond the g'-band half-light radius in massive hosts, offering explanation for the blue colors of their sites. SN Ic-BL and SN IIb host galaxies have lower abundances than SN Ic and SN Ib hosts, respectively.
- SN Ic often erupt at small offsets in massive galaxies with strong specific SFR, high oxygen abundance, and high extinction measured from fiber spectra. These fibers generally collect light from within the host's g'-band half-light radius. These explosion sites help to explain the high surface brightnesses near SN Ic explosion sites. High interstellar reddening helps to explain why the colors near SN Ic sites have colors similar to those of SN II, despite their hosts' high specific SFR.

The u'-z' color and u' surface brightness near SN explosion sites considerably separate SN IIb, SN Ic, and SN Ic (see Figure 2). SN Ic sites predominantly have high surface brightness, while SN IIb populate lower-surface brightness but extremely blue environments. SN Ib largely occupy the parameter space between the SN IIb and the SN Ib. By contrast, however, the explosion sites of SN II have no specific locus in the color-brightness plane.

These patterns suggest that the fraction of strippedenvelope SN to Type II SN may not vary strongly with environment. Perhaps the stars that may explode as SN IIb for one value of mass or metallicity instead explode as SN Ib or SN Ic in other environments where the chemistry, for example, is different.

### 9.2. SN Ib, SN IIb, and SN II Environments

The best-studied example of a Type IIb, SN 1993J, exploded at a distance of only 3.6 Mpc in M81 (Filippenko et al. 1993; Matheson et al. 2000), and archival imaging revealed that its progenitor was a K-type supergiant (Aldering et al. 1994). HST imaging after the SN disappeared found evidence for a Btype supergiant binary companion (Van Dyk et al. 2002; Maund et al. 2004). More recent studies of the sites of other SN IIb suggest, however, that a fraction of the SN IIb population may erupt from massive single stars (e.g., Crockett et al. 2008). Chevalier & Soderberg 2010 analyzed the radio emission, optical shock breakout, and nebular emission of a sample of SN IIb to constrain the extent of their progenitors' envelopes and the properties of their circumstellar material. They favor two progenitor populations: (a) extended progenitors (SN 1993J, SN 2001gd) with hydrogen envelope mass greater than  $\sim 0.1 M_{\odot}$  and slow, dense winds and (b) more compact and massive Wolf-Rayet progenitors (SN 1996cb, SN 2001ig, SN 2003bg, SN 2008ax, and SN 2008bo) with a less massive hydrogen envelope and lower density winds. PTF11eon/SN 2011dh, a SN IIb (Arcavi et al. 2011; Marion et al. 2011), was recently discovered by amateur astronomer Amadee Riou in M51, where preexplosion HST imaging exists of the SN site. Analysis of the archival images finds evidence for a supergiant with  $T_{eff} \sim 6000$  K at or near the SN site (Van Dyk et al. 2011; Maund et al. 2011). Radio and X-ray observations (Soderberg et al. 2011) and the optical spectroscopic and photometric evolution (Arcavi et al. 2011) both favor a compact progenitor, however, suggesting that this star may be a binary companion or not associated with the SN.

Our analysis finds three statistically significant, plausibly related patterns in the host environments of SN IIb: SN IIb environments are bluer than the environments of SN Ib, SN Ic, and SN II; their host galaxies are more metal-poor than SN Ib or SN Ic hosts; and their host galaxy interstellar extinction is less than that of SN (Ib+Ic). These trends are statistically significant even when we analyze only the locations of targeted SN.

An unambiguous implication of the exceptionally blue colors of SN IIb environments is that the Type IIb progenitor population is distinct from that of Type Ib explosions. Lack of hydrogen features near maximum light in SN Ib spectra may reflect a more extensive loss of the progenitor's hydrogen envelope. Comparatively metalpoor SN IIb host galaxies suggest that metals may play an important role in achieving this loss of the outer envelope.

The SN IIb population may erupt from a combination of massive single stars and progenitors in close binary systems, so a possibility is that the blue colors of SN IIb environments indicate higher binary fractions. Although the current examples of each class are few, future efforts may be able to draw distinctions between the environments of the compact and extended SN IIb progenitors proposed by Chevalier & Soderberg 2010.

Li et al. 2011a recently reported that the hosts of SN IIb detected by LOSS had greater K-band luminosities than SN II-P hosts (with p=6.9%). Lower SN IIb progenitor metallicities are consistent with the PTF's dimin-

ished fraction of SN IIb and SN Ic-BL in 'giant,' presumably metal-rich galaxies, than in 'dwarf' galaxies: 1 SN Ib, 3 SN IIb, and 2 SN Ic-BL, and 9 SN II in 'dwarf' galaxies, and 2 SN Ib, 2 SN IIb, 7 SN Ic, 1 SN Ic-BL and 42 SN II in 'giant' galaxies (Arcavi et al. 2010).

#### 9.3. SN Ic-BL Environments

Type Ic-BL are the SN that have been associated with coincident long duration gamma-ray burst (LGRB) explosions (Galama et al. 1998; Matheson et al. 2003; Stanek et al. 2003; Hjorth et al. 2003; Modjaz et al. 2006; see Woosley & Bloom 2006 and Modjaz 2011 for reviews). Modjaz et al. 2008 showed that SN Ic-BL with associated LGRB prefer more metal-poor environments than do SN Ic-BL without an LGRB (but see Levesque et al. 2010).

We find that host galaxies of SN Ic-BL (without an associated LGRB) follow a significantly more metal-poor distribution than the hosts of normal SN Ic (or SN Ib) explosions, even when only galaxy-impartial discoveries are considered. The colors of SN Ic-BL local environments also follow a bluer distribution than those of SN Ic, further evidence for different progenitor populations. SN Ic-BL host galaxies have strong specific SFRs, similar to those of normal SN Ic.

Lower Type Ic-BL progenitor oxygen abundances may imply reduced rates of wind-driven mass loss, potentially enabling SN Ic-BL progenitor to retain greater angular momentum (e.g., Kudritzki 2002; Heger et al. 2003; Eldridge & Tout 2004; Vink & de Koter 2005). High angular momentum before the explosion may be important to the production of high velocity ejecta (Woosley et al. 1993; Thompson et al. 2004). Nonetheless, the means by which SN Ic-BL progenitors shed their outer envelopes, if not through their high metallicity, needs explanation and may involve Roche lobe overflow (Podsiadlowski et al. 1992; Nomoto et al. 1995), stellar mergers (Podsiadlowski et al. 2010), or perhaps deep mixing.

Here our measurements support a picture where both SN Ib and SN Ic have more metal-rich hosts on average than SN Ic-BL, consistent with the host galaxy magnitudes measured by Arcavi et al. 2010. It presents a contrast with the results of Modjaz et al. 2011 who recently measured the oxygen abundances at the sites of SN Ic-BL, SN (Ib+IIb), and SN Ic. There the SN Ic-BL distribution falls intermediate between those of SN (Ib+IIb) and SN Ic, although it is more similar to the comparatively metal-poor SN (Ib+IIb) distribution and neither comparison is statistically significant. These contrasting trends may relate to fact that Modjaz et al. 2011 constructed their samples for each SN type from equal numbers of galaxy-impartial and targeted SN discoveries, or the inclusion of SN IIb (which we find inhabit metalpoor environments) with SN Ib. Modjaz et al. 2011 measurements were also taken at the explosion site, which may often differ significantly from the host abundance measured from SDSS fiber spectra (0.13 dex average disagreement with nuclear fiber measurements).

Svensson et al. 2010 found that host galaxies of LGRBs had smaller star masses than core-collapse SN hosts and had high surface brightness and more massive stellar populations. The only SN-LGRB that met our sample criteria, SN 2006aj, has low host stellar mass and

comparatively blue u'-z' color near the explosion site.

#### 9.4. SN Ib, SN Ic, and SN II Environments

In an earlier paper (Kelly et al. 2008), we showed that, while the positions of the other core-collapse SN follow the distribution of their hosts' light, Type Ic SN trace the brightest regions of their host galaxies in a pattern similar to that followed by LGRB (Fruchter et al. 2006). Possible explanations for this pattern include shorter lifetimes and higher masses of SN Ic progenitors (Raskin et al. 2008; Leloudas et al. 2010; Eldridge et al. 2011) as well as preference for metal-rich regions near the centers of hosts. Anderson & James 2008 showed, subsequently, that SN Ic also track their hosts'  $H\alpha$  emission more closely than SN II (their comparison with SN Ib lacked statistical significance).

The SDSS fiber spectra of core-collapse host galaxies, which generally sample inside of the g'-band half-light radius, reveal an increasing progression of specific SFR from SN II to SN Ib to SN Ic (and SN Ic-BL) hosts. This pattern persists when we study only the spectra from fibers targeting the host nucleus. SN Ic explode at comparatively small host offset, linking them to the strong star formation near their hosts' centers.

We find that the central star formation that yields SN Ic generally has high chemical abundance and extinction from interstellar dust. A SN Ic progenitor population tracking high metallicity would be expected to explode in massive galaxies with strong star formation in metalrich gas near their centers, the pattern we observe.

The colors of SN Ib and SN Ic explosion sites may offer evidence that their progenitors are also younger and more massive than the progenitors of SN II. The distribution of the apparent u'-z' color at SN Ib and SN Ic sites is similar to that at SN II sites. However, we find that SN (Ib+Ic) host galaxies have higher interstellar extinction ( $\Delta A_V \sim 0.5$  mag). This suggests that SN (Ib+Ic) sites have intrinsically bluer color than SN II sites, perhaps indicative of younger progenitor stellar populations.

SN Ib explosion sites have higher u'-band surface brightnesses than SN II sites, while SN Ib host galaxies generally have lower abundance than SN Ic in our sample. There is no statistically significant difference between the SN Ib and SN Ic host offset distributions in our sample (p=75%), which may imply that host offset cannot, on its own, explain the uniquely strong association of SN Ic with bright host galaxy pixels (Kelly et al. 2008).

While analyses of pre- and post-explosion imaging have not yet identified a progenitor of a SN Ib or SN Ic, red supergiants have been found at the sites of SN II-P explosions (e.g., Barth et al. 1996; Van Dyk et al. 1999, 2003b, 2003a, 2010; Smartt et al. 2001, 2003, 2004; Li et al. 2005, 2007; Maund & Smartt 2005). Smartt et al. 2009 favor a 8.5-16.5  $M_{\odot}$  mass range for SN II progenitors, although extinction along the line of sight to the progenitors is not well constrained (e.g., Walmswell & Eldridge 2011). Smith et al. 2010b note that Wolf Rayet stars in binary systems, possible progenitors of SN Ib and SN Ic, are expected to be less luminous than single Wolf Rayet stars. Brighter companions may outshine Wolf Rayet progenitors, although massgaining companions may, in some cases, explode first (Podsiadlowski et al. 1992; Eldridge et al. 2011). Even

for progenitors with close binary companions, metallicity and mass are expected to be important in determining the composition of the outer envelope, even though substantial mass loss may occur through Roche lobe overflow (Smith et al. 2010b; Yoon et al. 2010; Eldridge et al. 2011).

Prantzos & Boissier 2003 and Boissier & Prantzos 2009 found that SN (Ib+Ib/c+Ic) hosts have greater absolute  $M_B$  luminosities than SN II hosts. Prieto et al. 2008 previously compared the T04 metallicities of SN (Ib+Ic) and SN II host galaxies available in the SDSS DR4, finding p=5% evidence for a difference (they did not make note of the effect of AGN contamination). Van den Bergh 1997, Tsvetkov et al. 2004, Hakobyan et al. 2009, Anderson & James 2009, and Leaman et al. 2011 have found that SN (Ib+Ib/c+Ic) occur preferentially toward galaxy centers, where oxygen abundances are generally higher. Habergham et al. 2010, examining 178 host galaxies for evidence of interaction, and Anderson et al. 2011, in a study of SN sites in Arp 299, have explored explanations for these patterns.

Modjaz et al. 2011 find a significant difference ( $\sim$ 0.2 dex on average) between the oxygen abundances at the sites of 12 SN Ic and a mixed sample of 16 SN (Ib+IIb) for one of three oxygen abundance calibrations (although see Anderson et al. 2010 and Leloudas et al. 2011). When only abundances measured at the SN site from these three studies are compared, a significant difference between SN Ib and SN Ic metallicities computed with the Pettini & Pagel 2004 diagnostic is evident (M. Modjaz, private comm. and in prep.).

#### 9.5. SN IIn Environments

Among our set of host measurements, we find no statistically significant differences between the characteristics of SN IIn host environments and those of normal SN II.

Narrow line emission characterizes SN IIn spectra (Schlegel 1990) and is thought to be the result of the interaction of the ejecta with high density surrounding material. The existence of dense circumstellar material likely indicates strong pre-explosion mass loss (e.g., Chugai & Danziger 1994) and can increase the optical luminosity of the SN by thermalizing the emerging blast wave (e.g., Woosley et al. 2007; Smith et al. 2010a; van Marle et al. 2010).

Luminous Blue Variable (LBV) stars (e.g.,  $\eta$  Car), with their high mass loss rates (>  $10^{-4} M_{\odot} yr^{-1}$ ), have been suggested as candidate progenitors, although standard stellar modeling positions the LBV period before an ultimate Wolf-Rayet phase (e.g., Langer 1993; Maeder et al. 2005). Dwarkadas 2011 has recently suggested that observations may only present a convincing case for an LBV progenitor in the case of SN 2005gl (Gal-Yam et al. 2007; Gal-Yam & Leonard 2009). Other means of potentially producing regions of high density circumstellar material include, for example, pulsation-driven superwinds from red supergiants (RSGs) (Yoon & Cantiello 2010).

Our data suggest that SN IIn progenitors may have a range of properties (including mass) similar to those that contribute to the Type II population. Anderson & James 2009, who have also studied SN IIn explosion sites, found no significant difference between the mean radial offsets of 12 SN IIn and 35 SN IIP from the host galaxy center.

#### 10. CONCLUSIONS

SN IIb and SN Ic-BL erupt in environments with exceptionally blue color. SN IIb sites often have large host offsets, while SN Ic-BL generally have comparatively low mass host galaxies. By contrast, SN Ib and especially SN Ic environments have less extreme colors, similar to those of SN II sites, but with exceptionally high u'-band surface brightness. SN Ib and SN Ic generally erupt from regions within the g'-band half-light radii of high stellar mass galaxies. The colors and surface brightnesses of SN II as well as SN IIn environments show no strong distinguishing pattern.

The centers of SN Ic host galaxies are generally dusty, metal-rich, and have high specific SFR. Stronger interstellar extinction associated with SN Ic sites may explain why they are not bluer than SN II sites, despite higher specific SFR. The central regions of SN Ib host galaxies are less metal-rich and have smaller specific SFR than those of SN Ic hosts.

We find that SN IIb host galaxy spectra are more metal-poor than SN Ib host galaxy spectra, statistically significant even among only targeted SN discoveries. SN Ic-BL host galaxies are also less metal-rich than SN Ic host galaxies, even among only galaxy-impartial discoveries.

The specific SFR measured from fiber spectra is higher, on average, for types whose SN spectra indicate more complete loss of the progenitor's outer envelopes (e.g., SN Ic, SN Ic-BL). Even among only spectra of galaxy nuclei, SN (Ib+Ic) host spectra have stronger specific SFR than SN II host spectra.

The non-negligible fraction of stripped-envelope SN in low-metallicity host galaxies may indicate that some stripped-envelope SN have binary progenitors or, alternatively, single progenitors that collapse to a black hole.

Drout et al. 2010 have estimated the line-of-sight extinction instead inferred from the colors of SN light curves. The interstellar reddening we find from SDSS fiber spectra of SN Ib and SN Ic hosts yield consistent values of  $A_V$ .

AGN emission, which makes spectra unusable for abundance measurements and is found primarily in highmetallicity galaxies, leads us to exclude a larger fraction of SN II (21 $\pm 3\%$  (42/196)) than SN (Ib+Ic) host spectra (9 $\pm 4\%$  (4/47)). This produces an overestimate of SN (Ib+Ic) / SN II in high-metallicity environments from SDSS spectra alone. The ratio is lower when we use host stellar mass as an oxygen abundance proxy, impervious to AGN.

Stellar mass estimates, robust to AGN contamination, provide evidence that SN (Ib+Ic) / SN II increases in more massive, metal-rich galaxies, a trend that retains significance when we consider only targeted SN discoveries.

We find no strong difference between the environments of SN IIn and the normal SN II population.

Thanks especially to M. Modjaz for her perceptive comments and to D. Burke for help with both supporting observations and editorial feedback. We also thank P. Challis, H. Marion, N. Zakamska, G. Leloudas, S. Akiyama, S. Allen, R. Romani, S-C. Yoon, M. Blanton, N. Smith, A. von der Linden, M. Allen, and D. Applegate

for their advice and help. We acknowledge the MPA-JHU collaboration for making their catalog publicly available and Google Sky for help in producing color galaxy images. RPK's supernova research at the Center for Astrophysics is supported by NSF grant AST0907903.

Funding for the SDSS and SDSS-II has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the U.S. Department of Energy, the National Aeronautics and Space Administration, the Japanese Monbukagakusho, the Max Planck Society, and the Higher Education Funding Council for England.

The SDSS is managed by the Astrophysical Research Consortium for the Participating Institutions. The Participating Institutions are the American Museum of Natural History, Astrophysical Institute Potsdam, University of Basel, Cambridge University, Case Western Reserve University, University of Chicago, Drexel University, Fermilab, the Institute for Advanced Study, the Japan Participation Group, Johns Hopkins University, the Joint Institute for Nuclear Astrophysics, the Kavli Institute for Particle Astrophysics and Cosmology, the Korean Scientist Group, the Chinese Academy of Sciences (LAMOST), Los Alamos National Laboratory, the Max-Planck-Institute for Astronomy (MPIA), the Max-Planck-Institute for Astrophysics (MPA), New Mexico State University, Ohio State University, University of Pittsburgh, University of Portsmouth, Princeton University, the United States Naval Observatory, and the University of Washington.

Note. — The Off. Norm. column is the deprojected offset of the SN explosion site normalized by the host g'-band half-light radius. Method column denotes whether we designated the survey that discovered the SN as targeted (T) or galaxy-impartial (I). The Discoverer column is taken from the IAU catalog<sup>a</sup>.
